* Readings at midday
** At the soil surface just below mat of covering vegetation

March 11, 1957, with the adult emerging on or before March 21, 1957. A total of 128 days had been spent as a mature larvae and prepupa, as compared to an average of about ten days for other members of the same batch under the same conditions. This exception might be due to the specimen's doing little or no feeding, with consequently an arresting development long enough for later low temperatures to produce their effect.

The first five instars, released during the first week of January, 1957, had varying degrees of success in overwintering, and a portion of all of these instars successfully withstood the winter and emerged as adults during March, April, and May, 1957, the

mormal months for the first flight moths each spring, as indicated by light trap collections. Of the 100 larvae in the first instars released in early January, 1957, 55 became pupae between early March and mid-May, 1957, and 50 successfully mated and protected offspring. It might be added that the coldest temperator of the winter came in January after all larvae had been beased (see table 20). A summary of the foregoing data is given in table 21.

Winter Study Number Two

To augment the study discussed above and to prove that armyworm not only can, but does overwinter in Tennessee, searches were made for overwintering larvae at various nervals throughout the winter months from October, 1956, wough February 1957. Overwintering larvae were found at localities; namely, the Cherokee peach orchard on the localities; namely, the localities of the localities orchard on the localities orchard on the localities orchard on the localities orchard orchard

In all cases, the larvae were found only after diligent searchbeneath thick mats of grassy vegetation. Forty-two specimens in various stadia from five collections, one collection for month from October, 1956, through February, 1957, were in the study. The specimens were collected alive in the taken to the insectary immediately, and isolated in ounce metal salve boxes which in turn were placed in a gallon syrup can with a tight-fitting lid. This larger can was in the ground outside the insectary in an effort to match == nearly as possible prevailing soil temperatures, at the same affording the specimens protection from excess moisture, medaceous ground beetles, etc. Observations were made at bequent intervals, usually daily, of each specimen concerning stadium, physical condition, and amount of feeding. At each abservation, the larvae were given grass for food in surplus quantities and the temperature in the large container and in esurrounding soil just below the mat of covering vegetation was recorded (table 22).

Of the forty-two specimens used in this study, fifteen comdevelopment to the adult stage. Three of these fifteen proved not to be *P. unipuncta*, but a closely related the stage of the presence of the presence of the produce adult moths are unreliable. Consequently, only twelve specimens positively known to be *P. unipuncta* are

included in this analysis. This mistaken identity of field collected larvae led the writer to construct the key given on page 304.

A summary of the development of each of the twelve specimens culminating in the adult stage is given in table 23 and is shown graphically in figure 14.

Data from this study show that the development of the armyworm is arrested in the several larval stages thus extending the duration of development through the winter months. Consider specimen number one of table 23. This specimen spent virtually the entire fall and winter season in the third and fourth instars. It was captured as a third-instar larva on October 26.

molted to the fourth instar in which it remained until March 1957, for a total of 143 days in these two instars. The same required a total of 209 days, nearly seven months, complete its development from the third instar to adult. The greatest length of time spent in any one instar was by seeimen number four which remained in the fifth instar for total of 130 days after its capture in that stage.

Winter Study Number Three

This study was conducted in order to obtain records of the relative abilities of the various larval instars to withstand Tensee winter temperatures, to provide information on the released time of the armyworm when released under temperature conditions, and to supplement data of winter studies one and two.

During the early part of January, 1957, a total of 96 larvae isolated, one each according to instar into metal salve boxes. These boxes were in turn placed in larger syrup cans as already the cribed. Further procedure was identical to that of winter that two. This study differs from winter study one in that the area of that study were grouped and exposed to natural field reditions, while those of this study were isolated and exposed to natural temperatures. It differs from winter study two that larvae of that study were collected in the field from that larvae of that study were obligated whereas these were insectary reared before being isolated. Specimens this study were isolated as follows: January 2, 1957, 10 third-instar specimens; January 3, 1957, 50 first-instar specimens; January 5, 1957, 10 second-instar specimens and 10 fourth-inspecimens; January 7, 1957, 10 fifth-instar specimens; and January 12, 1957, 6 sixth-instar specimens.

The data of table 24 show that first instar larvae had little mess in surviving the winter temperatures. Only one specimen of the original fifty completed development and only three med for as long as the third instar. It seems that the species is destined to failure if eggs are deposited and hatch immediately meeding a killing frost. The remaining five instars were able survive the cold temperatures satisfactorily.

As this study progressed, it became apparent that the armywarm was capable of adding extra instars to its normal developmental stages. The one first-stage larva which succeeded in deloping to the adult stage had seven larval instars; nine of the released as thirds had seven instars, six had eight in-

stars, and one had nine instars; of those released as fourths, nine had seven instars and nine had eight instars; of those released as sixths, none had additional instars. This adding of extra instars could be a valuable mechanism for the armyworm for the survival of a long winter.

Table 25 gives the gross developmental time of all specimen which reached the pupal stage in this study. It also shows the number completing development in each group and the periods of adult emergence. From these data it can be seen that duration of development from the starting point of the various instars occurs in an orderly manner, taking the shortest time from the sixth instar and the longest from the first, with all intermediate instars in between. These data offer convincing evidence of the ability of the armyworm to extend developmental time by alternate periods of activity and inanition duration.

ing the winter months. In this connection it is interesting to note that an extended warm period in January, 1957, resulted in much feeding and molting in all instar groups. The data also shed some light on the reasons for the long spring flight of moths which result from the various stages of larvae present when the cold weather begins in the fall. All groups of moths of the second through sixth instar groups were mated and produced fertile eggs.

Figure 15 shows graphically the development records of the specimens given in table 25.

NATURAL ENEMIES OF THE ARMYWORM

During this study, extensive rearings of field-collected army-worms were made in an effort to determine the natural enemy complex and its effect upon the species. In addition to rearings, observations of those parasites present were made in the field during periods of abundance. Predators were not seriously studied except for occasional collections of predatory insects when they were conspicuously present. For this reason, information on predators in this section is taken largely from the literature.

Parasites

Thompson (1945) edited a catalogue of the parasites and predators of insect pests which had been recorded in the literature at that time. The parasites, but not the predators, of *Pseudaletia unipuncta* are included. This list is reproduced here and is arranged according to the families of the parasites. The reader is referred to the citation for authorities of the entries. Those species which have been reared from the armyworm by the writer are denoted with an asterisk (*).

| Total | 39 | 20 | | | |

The effect of parasitism on a population of armyworms may be shown by an observation made in a heavily infested nine-acre field of wheat by the author in Monroe County, Tennessee, June 1, 1956. On this day, armyworms were at their peak and pupation had already begun. The field of wheat had virtually been destroyed and the armyworms had begun their march toward a field of oats. The writer, with the help of Mr. Ray Stamey, Monroe County Agricultural Agent, pulled up six clusters of wheat stubble and made counts of organisms under each. The results are given in table 26. Assuming an average of two fly puparia to represent one armyworm, only 39 of 87 original armyworms would reach maturity in this sample. This would be a conservative estimate, since the pupa were not necessarily free of parasites and certainly not free of predatory attack.

More than one thousand armyworms from twenty-five field collections over a two-season period (1956-57) were individually

Two groups of Apanteles militaris were parasitized by the hyper-parasite Mesochorus discitergus.

reared by the writer and parasite data recorded (see tables 27 Lough 30). During 1956, 184 of 569 armyworms were parastilled (table 27), and in 1957, 199 of 479 showed parasitism Table 29). Populations for the two seasons were 32.3 and 41.5 ent parasitized respectively (tables 27 and 29). A total sixteen species of parasites were reared (see tables 28 and 30), eight of which were dipterous and a like number hymenoperous. The two orders were nearly equally represented in 1956, 52.17 per cent of all parasites being Diptera and 47.83 ent Hymenoptera (table 28); however, in 1957 hymenoperous parasites made up nearly 92 per cent of the total (table 30. Flies were numerous in the field during 1957, and many were seen on larvae of the armyworm; but a virus disease a heavy toll of the "worms," and the earlier development the hymenopterous parasites, before the "worms" died of sease, undoubtedly accounted for this great difference, since te flies had insufficient time to develop.

Parasites listed * Collections 100 per cent infected with a virus disease. emerged before the virus produced death of the host. All non-parasitized armyworms in these collections died from the virus as mature larvae.

The braconid, Apanteles militaris Walsh, was the predominant species among the hymenopterous insects, accounting for 27 per cent of all parasitism in 1956 and 36 per cent in 1957. Among the flies, Winthemia rufopicta Big., a larvaevorid (Tachinidae), dominated with 12 per cent of the total 1956 parasites, and was heavily represented among armyworm populations in 1957, though records indicated only 7.1 per cent. The low percentage of Diptera in 1957 was undoubtedly due to the early death of armyworm hosts from a virus infection.

A discussion of each parasite reared from the armyworm by the writer follows.

Hymenoptera: Braconidae

Apanteles militaris Walsh. Of all the parasites of P. unipuncta, the most effective, as previously stated, is Apanteles militaris Walsh (figures 16, 17, and 18), which was reared from 11.7 per cent of all armyworms collected over a two-season period and which accounted for approximately 32 per cent of total parasites reared from the armyworm during the same period.

Tower (1916) states that armyworms parasitized by A. militaris eat approximately half as much as do non-parasitized larvae during the same period, and that it seems conclusive that parasitism by this species is beneficial in the generation attacked. The parasite ultimately kills its host, thereby being beneficial

Table 30. Relative Numbers and Percentages of Parasites Reared From the Armyworm During 1957.

 One specimen of Rogas terminalis was parasitized by the hyper-parasite, Mesochorus sp.

also in preventing many worms from maturing and beginning a new generation.

Armyworms parasitized by A. militaris show no signs of their plight until nearly mature when they become sluggish, and death comes only after the parasite larvae have emerged and spun their cocoons. Emergence of the A. militaris larvae from the armyworm host takes place with all larvae coming out at essentially the same time (figure 17). Cocoon spinning begins immediately after emergence from the host and is completed within a few hours time. The parasites emerge in large numbers from full grown or nearly full grown armyworms and spin white silken cocoons in a mass side by side. The cocoons average about 3.0 mm. in length and 1.3 mm. in width. Figure 18 shows a typical mass of cocoons. The number of cocoons spun from each of 49 armyworm larvae during 1956 ranged from 6 to 101 and averaged 49.

In the presence of adults of A. militaris, armyworms exhibit a nervous behavior. The female parasite attacks the armyworm almost immediately upon contact, and is capable of depositing everal scores of eggs with one quick thrust of the ovipositor in any available part of the armyworm host. The whole act of exposition is a matter of seconds. The victim turns upon beattacked and spits, sometimes drowning the assailant in a large bubble of dark green fluid. The writer has observed a large
